

Influence Function and Efficiency of the Minimum Covariance Determinant Scatter Matrix Estimator

Christophe Croux *

Gentiane Haesbroeck [†]

Abstract

The Minimum Covariance Determinant (MCD) scatter estimator is a highly robust estimator for the dispersion matrix of a multivariate, elliptically symmetric distribution. It is fast to compute and intuitively appealing. In this note we derive its influence function and compute the asymptotic variances of its elements. A comparison with the one step reweighted MCD and with S-estimators is made. Also finite-sample results are reported.

Keywords: Influence Function, Minimum Covariance Determinant Estimator, Robust Estimation, Scatter Matrix.

1 Introduction

The classical average and covariance matrix are key ingredients in almost all multivariate statistical methods. However, they are extremely sensitive to outliers. It is therefore important to consider robust alternatives for these estimators, which can be used to obtain robust procedures in principal component analysis, factor analysis,... Among the robust alternatives to the classical estimators, the Minimum Volume Ellipsoid (MVE) introduced by Rousseeuw (1985) is probably the most widely known and used. It consists of taking as location estimator the center of the smallest regular ellipsoid containing half the points of the data set. The scatter estimator is then defined by the shape matrix of that ellipsoid. However, it was shown that the MVE estimator is not \sqrt{n} consistent (Davies, 1992a), making it less attractive for efficiency reasons. A robust estimator which has the normal rate of convergence is the Minimum Covariance Determinant (MCD) estimator of Rousseeuw (1985). The location and scatter estimates are given by the average and covariance matrix computed on that half of the data which attain the smallest determinant of their covariance matrix. Until quite recently, the major drawback of the MCD estimator was its computation time. Rousseeuw and Van Driessen (1997) however, proposed a new algorithm to compute MCD, which turns out to be extremely fast, even in high dimensions.

Theoretical properties of the MCD estimator have been investigated in Butler (1982) and Butler, Davies and Jhun (1993), but the asymptotic distribution of the scatter part of the MCD remained unknown. In the particular case of one dimension the influence function of the MCD scale was computed by (Croux and Rousseeuw, 1992). In this paper we compute the influence function of the scatter part of the MCD in arbitrary dimensions. Section 2 defines the MCD-functional and gives this influence function while in Section 3 asymptotic variances are computed. Section 4 uses results of Lopuhaä (1997) to show that one step reweighted covariances, starting from MCD based weights, combines the breakdown properties of the MCD estimator while achieving a better relative efficiency. However, this reweighting does not yield an estimator as efficient as the S-estimator of scatter. The following section presents finite sample results based on simulation while Section 6 concludes.

2 Influence Function

For a finite sample of observations $\{x_1, \dots, x_n\}$ in \mathbb{R}^p the MCD is determined by selecting that subset $\{x_{i_1}, \dots, x_{i_h}\}$ of size h , with $1 \leq h \leq n$, which minimizes the generalized variance (which is the determinant of the covariance matrix computed from the subset) among all possible subsets of size h . The location estimator is then defined as

$$\hat{\mu}_n = \frac{1}{h} \sum_{j=1}^h x_{i_j}$$

and the estimator of scatter by

$$\hat{\Sigma}_n = c_p \frac{1}{h} \sum_{j=1}^h (x_{i_j} - \hat{\mu}_n)(x_{i_j} - \hat{\mu}_n)^t,$$

where c_p is a consistency factor. The choice $h = [(n + p + 1)/2] \approx 0.5n$ is commonly preferred since it yields the highest possible breakdown point (Lopuhaä and Rousseeuw 1991). The breakdown point of a multivariate scale estimator is defined as the smallest fraction of observations that you need to replace to arbitrary position before the estimated scatter explodes (its biggest eigenvalue tends to infinity) or implodes (its smallest eigenvalue tends to zero). Another default value is $h \approx 0.75n$, yielding a better compromise between efficiency/stability and high breakdown. To derive the influence function of an estimator, we need a proper definition for its functional form. In Butler, Davies and Jhun (1993, BDJ from now on) a definition appropriate for continuous distributions is given, which we will generalize afterwards to arbitrary distributions G . This is necessary since we will apply the MCD to point contaminated distributions.

Denote by $0 < \alpha < 1$ the mass of the data not determining the MCD, which will result in an estimator with (asymptotic) breakdown point $\min(\alpha, 1 - \alpha)$. Define

$$\mathcal{D}_G(\alpha) = \{A | A \subseteq \mathbb{R}^p \text{ measurable and bounded with } P_G(A) = 1 - \alpha\}, \quad (2.1)$$

and for every $A \in \mathcal{D}_G(\alpha)$, the average and covariance matrix computed over this set will be denoted by

$$T_A(G) = \frac{\int_A y dG(y)}{1 - \alpha} \quad (2.2)$$

and

$$\Sigma_A(G) = \frac{\int_A (y - T_A(G))(y - T_A(G))^t dG(y)}{1 - \alpha}. \quad (2.3)$$

The set A is called an MCD-solution if

$$\det(\Sigma_A(G)) \leq \det(\Sigma_{\tilde{A}}(G)), \quad (2.4)$$

for every other $\tilde{A} \in \mathcal{D}_G(\alpha)$. The MCD estimators at the theoretical distribution are then defined by

$$T(G) = T_A(G) \text{ and } \Sigma(G) = c_\alpha \Sigma_A(G) \quad (2.5)$$

for an MCD solution A . The constant c_α can be chosen in such a way that consistency will be obtained at the specified model.

A problem may arise with the above definition when the distribution G is not continuous, in which case $\mathcal{D}_G(\alpha)$ may be empty. Therefore define

$$\begin{aligned} \tilde{\mathcal{D}}_G(\alpha) = & \{(A, x) | A \subseteq \mathbb{R}^p \text{ measurable and bounded, } x \in \mathbb{R}^p \setminus A \\ & \text{and } \exists 0 \leq \delta \leq P_G(\{x\}) : P_G(A) + \delta = 1 - \alpha\}, \end{aligned}$$

which is never empty. Furthermore, for every $(A, x) \in \tilde{\mathcal{D}}_G(\alpha)$ define (with $\delta = 1 - \alpha - P_G(A)$)

$$T_{(A,x)}(G) = \frac{\int_A y dG(y) + \delta x}{1 - \alpha}, \quad (2.6)$$

and

$$\Sigma_{(A,x)}(G) = \frac{\int_A (y - T_{(A,x)}(G))(y - T_{(A,x)}(G))^t dG(y) + \delta (x - T_{(A,x)}(G))(x - T_{(A,x)}(G))^t}{1 - \alpha}. \quad (2.7)$$

(Since A is bounded all the above quantities are well defined). We say that $(A, x) \in \tilde{\mathcal{D}}_G(\alpha)$ is an MCD solution if

$$\det(\Sigma_{(A,x)}(G)) \leq \det(\Sigma_{(\tilde{A}, \tilde{x})}(G)), \quad (2.8)$$

for every $(\tilde{A}, \tilde{x}) \in \tilde{\mathcal{D}}_G(\alpha)$. The MCD estimators at the population level are then given by

$$T(G) = T_{(A,x)}(G) \text{ and } \Sigma(G) = c_\alpha \Sigma_{(A,x)}(G), \quad (2.9)$$

for an MCD solution (A, x) . Thus, the MCD solution determines a region $B = A \cup \{x\}$, with $P_G(A) \leq 1 - \alpha \leq P_G(B)$. By giving a lower mass to the atom x , we are in a certain way interpolating between the two sets A and B . For ease of notation, we will write $T_A(G)$ and $\Sigma_A(G)$ instead of $T_{(A,x)}(G)$ and $\Sigma_{(A,x)}(G)$ whenever $P_G(A) = 1 - \alpha$ for a couple $(A, x) \in \tilde{\mathcal{D}}_G(\alpha)$.

Table 1: Particular values of c_α and q_α at the normal model.

α		$p = 2$	$p = 3$	$p = 5$	$p = 10$	$p = 30$
0.25	c_α	1.859	1.609	1.412	1.256	1.130
	q_α	2.773	4.108	6.626	12.549	37.799
0.5	c_α	3.259	2.457	1.912	1.531	1.257
	q_α	1.386	2.366	4.351	9.342	29.336

In this paper we will focus on the problem of estimating the parameters μ and Σ of the distribution $F_{\mu,\Sigma}$ with density

$$f_{\mu,\Sigma}(x) = \frac{g((x - \mu)^t \Sigma^{-1} (x - \mu))}{\sqrt{\det(\Sigma)}} \quad (2.10)$$

with $\mu \in \mathbb{R}^p$ and $\Sigma \in \text{PD}(p)$, the set of all positive definite matrices of size p .

The function g is assumed to be known and to have a strictly negative derivative g' , so that $F_{\mu,\Sigma}$ belongs to a parametric class of elliptically symmetric, unimodal distributions. It is shown in Section 2 of BDJ that for this distribution the MCD-problem has a unique solution given by the ellipsoid

$$A(F_{\mu,\Sigma}) = \{z \in \mathbb{R}^p | (z - \mu)^t \Sigma^{-1} (z - \mu) \leq q_\alpha\} \quad (2.11)$$

where $G(t) = P_{F_{0,I}}(Z^t Z \leq t)$ and $q_\alpha = G^{-1}(1 - \alpha)$, with corresponding MCD-functionals

$$\begin{aligned} T(F_{\mu,\Sigma}) &= \mu \\ \Sigma(F_{\mu,\Sigma}) &= \left(\frac{c_\alpha}{1 - \alpha} \int_{z^t z \leq q_\alpha} z_1^2 dF_{0,I}(z) \right) \Sigma. \end{aligned}$$

To obtain Fisher-consistency at this model, it suffices to set

$$c_\alpha = \frac{1 - \alpha}{\int_{z^t z \leq q_\alpha} z_1^2 dF_{0,I}(z)} = (1 - \alpha) \left\{ \frac{\pi^{\frac{p}{2}}}{\Gamma(\frac{p}{2} + 1)} \int_0^{\sqrt{q_\alpha}} r^{p+1} g(r^2) dr \right\}^{-1}.$$

Table 1 gives several values of the constants c_α and q_α for different values of p and α at the normal model.

Since the MCD is affine equivariant we will only derive the influence function at the model distribution $F = F_{0,I_p}$. Consider the *contaminated distribution*

$$F_{\varepsilon,x} = (1 - \varepsilon)F + \varepsilon\Delta_x,$$

where Δ_x is a Dirac measure putting all its mass at $x \in \mathbb{R}^p$. The influence function measures the sensitivity of the MCD-functional to small amounts of contamination in the distribution:

$$IF(x, \Sigma, F) = \lim_{\varepsilon \downarrow 0} \frac{\Sigma(F_{\varepsilon, x}) - \Sigma(F)}{\varepsilon}.$$

More about the use and interpretation of influence functions can be found in Hampel et al (1986). The derivation of the influence function for the MCD relies on the following proposition, which says that the MCD solution at the contaminated distribution $F_{\varepsilon, x}$ is still determined by an ellipsoid. (This can even be shown to be true for any distribution G , and was already proven for empirical distribution functions by BDJ page 1392.)

Proposition 1. *Take $0 < \varepsilon < \min(\alpha, 1 - \alpha)$, $x \in \mathbb{R}^p$ and consider the contaminated distribution $F_{\varepsilon, x}$. For any MCD-solution $(A, y) \in \tilde{\mathcal{D}}_{F_{\varepsilon, x}}(\alpha)$, there exists an open ellipsoid \mathcal{E} such that:*

$$\mathcal{E} \in \mathcal{D}_{F_{\varepsilon, x}}(\alpha), \quad T_{\mathcal{E}}(F_{\varepsilon, x}) = T_{(A, y)}(F_{\varepsilon, x}) \quad \text{and} \quad \Sigma_{\mathcal{E}}(F_{\varepsilon, x}) = \Sigma_{(A, y)}(F_{\varepsilon, x})$$

or, in the special case that x lies at the border of \mathcal{E} ,

$$(\mathcal{E}, x) \in \tilde{\mathcal{D}}_{F_{\varepsilon, x}}(\alpha), \quad T_{(\mathcal{E}, x)}(F_{\varepsilon, x}) = T_{(A, y)}(F_{\varepsilon, x}) \quad \text{and} \quad \Sigma_{(\mathcal{E}, x)}(F_{\varepsilon, x}) = \Sigma_{(A, y)}(F_{\varepsilon, x}).$$

The next theorem gives the influence function of the scatter matrix part of the MCD functional. To facilitate the interpretation, we give separate expressions for the diagonal and off-diagonal elements. All proofs are kept for the Appendix.

Theorem 1. *With the notations from above, we have that*

$$\begin{aligned} IF(x, \Sigma_{ii}, F) &= \frac{1}{b_1} \left\{ \frac{c_\alpha}{1 - \alpha} x_i^2 I(\|x\|^2 \leq q_\alpha) + \frac{b_2}{b_1 - pb_2} \frac{c_\alpha}{1 - \alpha} \|x\|^2 I(\|x\|^2 \leq q_\alpha) \right. \\ &\quad \left. + \frac{b_1}{b_1 - pb_2} \left[\frac{c_\alpha}{1 - \alpha} \frac{q_\alpha}{p} (1 - \alpha - I(\|x\|^2 \leq q_\alpha)) - 1 \right] \right\} \end{aligned} \quad (2.12)$$

$$IF(x, \Sigma_{ij}, F) = \frac{x_i x_j}{-2c_3} I(\|x\|^2 \leq q_\alpha) \quad \text{if } i \neq j \quad (2.13)$$

where the constants b_1, b_2, c_2, c_3 and c_4 are determined by the relations

$$\begin{aligned} c_2 &= \frac{\pi^{\frac{p}{2}}}{\Gamma(\frac{p}{2} + 1)} \int_0^{\sqrt{q_\alpha}} r^{p+1} g'(r^2) dr \\ c_3 &= \begin{cases} \frac{\pi^{\frac{p}{2}}}{(p+2)\Gamma(\frac{p}{2} + 1)} \int_0^{\sqrt{q_\alpha}} r^{p+3} g'(r^2) dr & \text{if } p \geq 2 \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

$$\begin{aligned}
c_4 &= \frac{3\pi^{\frac{p}{2}}}{(p+2)\Gamma(\frac{p}{2}+1)} \int_0^{\sqrt{q_\alpha}} r^{p+3} g'(r^2) dr \\
b_1 &= \frac{c_\alpha(c_3 - c_4)}{1 - \alpha} \\
b_2 &= \frac{1}{2} + \frac{c_\alpha}{1 - \alpha} \left[c_3 - \frac{q_\alpha}{p} \left(c_2 + \frac{1 - \alpha}{2} \right) \right].
\end{aligned}$$

It follows immediately that the MCD scale estimator has a bounded influence function, which is redescending to zero for the off-diagonal elements, but not for the on-diagonal elements. In Figure 1 the influence functions $IF(x, \Sigma_{11}, F)$ and $IF(x, \Sigma_{12}, F)$ are pictured for $p = 2$ and $\alpha = 0.25$ at the normal model. The functions are smooth, except for a jump at the circle with radius $\sqrt{q_\alpha}$. If we denote θ the angle of x with the first axis, then the discontinuity in $IF(x, \Sigma_{11}, F)$ is upwards for $\theta < \pi/4$ and downwards for $\theta > \pi/4$. The maximal value is attained at $(\sqrt{q_\alpha}, 0)$. The off-diagonal influence function is maximal at $(\sqrt{q_\alpha/2}, \sqrt{q_\alpha/2})$.

INSERT FIGURE 1 HERE

Remark 1: For $p > 1$ one can see that $c_4 = 3c_3$ and the obtained influence function can be rewritten in the more compact form

$$IF(x, \Sigma, F) = \frac{-1}{2c_3} xx^t I(\|x\|^2 \leq q_\alpha) + w(\|x\|) I_p,$$

where w is a certain real valued function.

Remark 2: The classical estimator of a scatter matrix is the covariance matrix $C(G)$, defined at the population level by

$$C(G) = c_0 \int_{\mathbb{R}^p} (x - \mu(G))(x - \mu(G))^t dG(x), \quad (2.14)$$

where $\mu(G) = \int_{\mathbb{R}^p} x dG(x)$ and the consistency factor c_0 equals $E_F(X_i^2)^{-1}$ where X_i is a component of the vector X . It appears as a limit case of the MCD for α , the mass of the data “discarded” by the MCD, tending to zero. Note that C is only well defined for distributions with a second moment, whereas the MCD functionals are properly defined for arbitrary distributions. It is not so difficult to check that

$$\lim_{\alpha \downarrow 0} IF(x, \Sigma, F) = c_0 xx^t - I = IF(x, C, F).$$

Remark 3: In the case $p = 1$, (2.12) can be rewritten as

$$IF(x, \Sigma, F) = \left\{ \int_{-\sqrt{q_\alpha}}^{\sqrt{q_\alpha}} t^2 dF(t) \right\}^{-1} \{I(|x| \leq \sqrt{q_\alpha})(x^2 - q_\alpha) + (1 - \alpha)q_\alpha\} - 1,$$

with $\sqrt{q_\alpha} = F^{-1}(1 - \frac{\alpha}{2})$. The parameter $S = \sqrt{\Sigma}$ measures here the dispersion of the univariate distribution F . This above expression corresponds with the results of Croux and Rousseeuw (1992).

Remark 4: The computation of the influence function of the location part of MCD is relatively simple, and the result is implicitly contained in BDJ:

$$IF(x, T, F) = \left(\frac{-2}{1 - \alpha} \int_{z^t z \leq q_\alpha} z z^t g'(z^t z) dz \right)^{-1} \frac{x}{1 - \alpha} I(\|x\|^2 \leq q_\alpha).$$

Observe that $IF(x, T, F)$ becomes zero when x is outside the ball of radius $\sqrt{q_\alpha}$, illustrating that MCD-location “rejects” huge outliers. This is in contrast with MCD-scatter, where these outliers still have a (bounded) influence on the diagonal elements of the scatter matrix.

Attention in this paper is restrained to the scale case, since highly robust affine equivariant estimation of location is less crucial than for scatter. It is well known (Rousseeuw and Leroy page 271, 1987) that with an *orthogonally* equivariant location estimator T_0 and an *affine* equivariant scatter matrix estimator Σ_0 , an affine equivariant location estimator T_1 is easily obtained by setting

$$T_1(x_1, \dots, x_n) = \Sigma_0^{1/2} T_0(\Sigma_0^{-1/2} x_1, \dots, \Sigma_0^{-1/2} x_n).$$

Lopuhää (1992) proved that T_1 inherits the robustness properties of the initial estimators Σ_0 and T_0 . Furthermore, orthogonally equivariant location estimators which have high breakdown point, good efficiency properties and which are very fast to compute have been proposed in the literature (e.g. Hössjer and Croux, 1994).

Remark 5: Strictly speaking, Theorem 1 only gives an almost sure expression for the influence function. In case that $\|x\|^2 = q_\alpha$, a zero probability event, one has $IF(x, \Sigma, F) = c_\alpha x x^t - I$. This follows quite immediately from the special case of Proposition 1.

3 Asymptotic Variances

It is argued in BDJ that the MCD scatter matrix is asymptotically normal, but no expression for the asymptotic variance has been derived. In this Section we will compute asymptotic

variances by means of

$$\text{ASV}(\Sigma_{ij}, F) = \int_{\mathbb{R}^p} IF^2(x, \Sigma_{ij}, F) dF(x) \quad (3.1)$$

for $1 \leq i, j \leq n$. The normal location-scale model (2.10) with

$$g_\Phi(t) = \frac{1}{(2\pi)^{\frac{p}{2}}} \exp\left(-\frac{t}{2}\right)$$

is without any doubt the most important case. We will denote $F = \Phi$ the multivariate standard normal distribution. Explicit expressions for the asymptotic variances can be worked out:

$$\begin{aligned} \text{ASV}(\Sigma_{ii}, \Phi) &= \frac{(1 - \alpha)b_1^2 \left(\alpha \left(\frac{c_\alpha q_\alpha}{p} - 1 \right)^2 - 1 \right) - 2c_3 c_\alpha^2 (3(b_1 - pb_2)^2 + (p + 2)b_2(2b_1 - pb_2))}{(b_1(b_1 - pb_2)(1 - \alpha))^2} \\ \text{ASV}(\Sigma_{ij}, \Phi) &= -\frac{1}{2c_3} \text{ if } i \neq j. \end{aligned}$$

Please note that the above expressions vary both with the dimension p and with the trimming proportion α . The limit case $\alpha = 0$ gives the asymptotic variances of the usual covariance matrix:

$$\text{ASV}(C_{ii}, \Phi) = 2 \text{ and } \text{ASV}(C_{ij}, \Phi) = 1 \text{ for } i \neq j.$$

This enables us to compute relative efficiencies of the MCD-estimator at a model distribution F with respect to the classical covariance estimator as ratios

$$\text{ARE}(\Sigma_{ij}, F) = \frac{\text{ASV}(C_{ij}, F)}{\text{ASV}(\Sigma_{ij}, F)} \quad \forall 1 \leq i, j \leq p. \quad (3.2)$$

INSERT FIGURE 2 HERE

Figure 2 illustrates how the efficiencies $\text{ARE}(\Sigma_{ij}, \Phi)$ vary with α and p under the normal model. First of all, note that efficiency decreases as the breakdown point increases, showing a conflict between efficiency and high breakdown. Choosing the highest possible breakdown point ($\alpha = 0.5$) results in a severe loss of efficiency. The suggestion to take $\alpha = 0.25$ as a compromise between efficiency and robustness finds its motivation here: the corresponding estimator can still cope with realistic amounts of contamination in the data, but is much more precise (when no outliers are present) than the usual choice $\alpha = 0.5$.

Figure 2 also reveals that the efficiencies of MCD are increasing with the dimension. Even more, one can formally prove that

$$\lim_{p \rightarrow \infty} \text{ARE}(\Sigma_{ij}, \Phi) = \frac{1}{1 - \alpha} \quad \forall 1 \leq i, j \leq p. \quad (3.3)$$

Result (3.3) can be understood intuitively: every observation $X_i = (X_{i1}, \dots, X_{ip})^t$ following the reference distribution Φ lies at a squared distance $X_{i1}^2 + \dots + X_{ip}^2 \approx p$ from the origin, when p is large. (Here we used the strong law of large numbers and independency of the different components of X_i .) This implies that all observations are “equally likely” to constitute the subset of size $n(1 - \alpha)$ whose covariance matrix will yield the MCD-scatter estimator. We conclude that, at the reference distribution Φ and for p huge, the MCD is like a usual covariance matrix but computed from a random subsample of size $n(1 - \alpha)$ instead of size n , which explains (3.3). The convergence in (3.3) is however rather slow, as is shown by the Table below for $\alpha = 0.25$:

p	100	10^3	10^4	10^7	∞
$\text{ARE}(\Sigma_{ii}, \Phi)$	0.6559	0.7210	0.7415	0.7497	0.75
$\text{ARE}(\Sigma_{ij}, \Phi)$	0.6542	0.7209	0.7411	0.7497	0.75

Another class of multivariate elliptically symmetric distributions which is regularly used (e.g. in econometrics), is generated by setting in (2.10)

$$g_{F_\nu}(t) = \frac{\Gamma(\frac{p+\nu}{2})}{\Gamma(\frac{\nu}{2})(\pi\nu)^{\frac{p}{2}}} \frac{1}{(1 + \frac{t}{\nu})^{\frac{p+\nu}{2}}}.$$

The corresponding model distribution is a multivariate Student with ν degrees of freedom. Consistency factors and influence functions can be easily computed, using symbolic computation software. Moreover, asymptotic variances have been computed by (3.1) for the reference distribution F_ν , using numerical integration and a lot of computation time in order to obtain accurate results. The classical covariance estimator (2.14) needs now to be premultiplied with $c_0 = \frac{\nu-2}{\nu}$, and has asymptotic variances $\text{ASV}(C_{ii}, F_\nu) = \frac{2\nu-2}{\nu-4}$ and $\text{ASV}(C_{ij}, F_\nu) = \frac{\nu-2}{\nu-4}$ for $\nu > 4$ and $i \neq j$.

Tables 2 and 3 list asymptotic relative efficiencies of the elements of the MCD estimator at some Student distributions F_ν with ν degrees of freedom, for several values of p and for $\alpha = 0.25$ and 0.5 . Corresponding values for the normal distribution (which is the limit case

Table 2: Asymptotic Relative Efficiencies of a diagonal element of the MCD scatter matrix estimator w.r.t. the classical covariance estimator at Student distributions for several values of p with $\alpha = 0.25$ and 0.5 .

		$p = 2$	$p = 3$	$p = 5$	$p = 10$	$p = 30$

	F_8	0.069	0.130	0.232	0.382	0.565
	F_{15}	0.047	0.090	0.163	0.276	0.430
	Φ	0.033	0.063	0.113	0.191	0.304

for $\nu \rightarrow \infty$) are also reported. One sees that at these heavier tailed distributions it remains true that the efficiency gain taking $\alpha = 0.25$ instead of the usual $\alpha = 0.5$ is considerable. Moreover, at the Student distribution with 5 degrees of freedom the MCD (with $\alpha = 0.25$) is even more efficient than the classical covariance matrix estimator.

Remark : At the Cauchy distribution (which is a Student distribution with 1 degree of freedom) the ARE as defined in (3.2) cannot be computed. It is however possible to compare the asymptotic variances with the Cramer-Rao lower bound, which yields the efficiencies (only reported for the diagonal elements) in Table 4. The results are less clearcut here: the best choice in high dimensions is $\alpha = 0.5$. Notice that the efficiencies in Table 4 decrease

Table 4: Asymptotic Efficiencies of a diagonal element of the MCD scatter matrix estimator at the Cauchy distribution for several values of p with $\alpha = 0.25$ and 0.5 .

	$p = 2$	$p = 3$	$p = 5$	$p = 10$	$p = 30$
$\alpha = 0.25$	0.443	0.347	0.279	0.229	0.198
$\alpha = 0.5$	0.356	0.322	0.294	0.266	0.247

with the dimension.

4 Related Robust Estimators of Scatter

Since the efficiency of high breakdown methods can be quite low, it is often recommended to compute reweighted versions of them, which maintain the breakdown point of the initial estimators while attaining (hopefully) a better efficiency. Quite recently, Lopuhaä (1997) derived asymptotic properties of reweighted multivariate estimators of location and scatter. Denote (T^0, Σ^0) initial robust estimators of multivariate location and scatter. For a sample $\{x_1, \dots, x_n\}$ one step reweighted estimators are computed as

$$T^1 = \frac{\sum_{i=1}^n w_i x_i}{\sum_{i=1}^n w_i} \quad \text{and} \quad \Sigma^1 = c_1 \frac{\sum_{i=1}^n w_i (x_i - T^1)(x_i - T^1)^t}{\sum_{i=1}^n w_i} \quad (4.1)$$

where the weights are computed from the initial estimators by

$$w_i = w \left((X_i - T^0)^t (\Sigma^0)^{-1} (X_i - T^0) \right)$$

with $w : [0, \infty[\rightarrow \mathbb{R}$ a suitable weight function.

A simple, but common choice is to take

$$w(t) = I_{[0, q_\delta]}(t) \quad \text{with} \quad q_\delta = G^{-1}(1 - \delta), \quad (4.2)$$

where $G(u) = P_F(X^t X \leq u)$. At the p -dimensional normal model we have $q_\delta = \chi_{p, 1-\delta}^2$. The consistency factor c_1 is given by

$$c_1 = (1 - \delta) \left\{ \frac{\pi^{\frac{p}{2}}}{\Gamma(\frac{p}{2} + 1)} \int_0^{\sqrt{q_\delta}} r^{p+1} g(r^2) dr \right\}^{-1}.$$

The influence function of Σ^1 at the model distribution F for the weight function (4.2) follows from Lopuhaä (1997):

$$IF(x, \Sigma^1, F) = \frac{d_2 + 2d_3}{d_2} \left(IF(x, \Sigma^0, F) + \frac{1}{2} \text{trace}(IF(x, \Sigma^0, F)) I \right) + \frac{1}{d_2} I(x^t x \leq q_\delta) x x^t - I,$$

where the constant d_2 equals $(1 - \delta)c_1^{-1}$ and the expression for d_3 is the same as for c_3 (given in Theorem 1) but with α replaced by δ .

Taking the MCD estimator for (T^0, Σ^0) and $\delta = 0.025$ in (4.2) is advocated and used by (Rousseeuw and Van Driessen 1997) and we denote the resulting estimator by MCD^1 . Figure 2 gives the influence functions for a diagonal and an off-diagonal element of the MCD^1 scatter estimator in the bivariate case for $\alpha = 0.25$. We observe two jumps: one due to the discontinuity of the weight function and the other due to the discontinuity in the influence function of the initial MCD estimator. Note that the influence of extreme outliers on MCD^1 is smaller than on the ordinary MCD.

INSERT FIGURE 3 HERE

One could also iterate the process and define MCD^2 as a reweighted estimator using MCD^1 as starting estimator in (4.1). The general belief is that reiterating could increase efficiency, but at the cost of a higher bias (Rousseeuw and Croux, 1994).

As a competitor for the MCD estimator, S-estimators will be considered. Recall that the S -functional $(t(G), S(G))$ is defined as the minimizer of $\det(S)$ subject to

$$\int \rho \left(\sqrt{(x-t)^t S^{-1} (x-t)} \right) dF(x) = b_0$$

among all (t, S) , with $t \in \mathbb{R}^p$ and $S \in \text{PD}(p)$. The function $\rho : [0, \infty[\rightarrow [0, +\infty[$ should be bounded, increasing and sufficiently smooth. A standard choice is Tuckey's biweight function:

$$\rho_c(y) = \min\left(\frac{y^2}{2} - \frac{y^4}{2c^2} + \frac{y^6}{6c^4}, \frac{c^2}{6}\right).$$

To obtain Fisher consistency at the model distribution F take $b_0 = E_F[\rho_c(\|x\|)]$. In order to attain a breakdown point of α , one needs to select the constant c as the solution of the equation $b_0 = \alpha \rho_c(\infty)$. The reweighted version of an S-estimator which will be considered, S^1 , is obtained using the biweight S as initial estimator in (4.1). Asymptotics of S-Estimators were derived by Davies (1987) and expression for the influence function can be found in Lopuhaä (1989). Figure 4 pictures $IF(x, S_{11}, \Phi)$ and $IF(x, S_{12}, \Phi)$, for the 25% breakdown biweight S-estimator. Comparison with Figure 1 reveals that the IF for the S-estimator is a smoothed version of the MCD's influence function.

INSERT FIGURE 4 HERE

A comparative study of the asymptotic efficiencies of the elements of the scatter matrix estimators MCD¹, MCD², S , and S^1 has been done, of which the results are reported in Tables 5 and 6. As before, the two cases $\alpha = 25\%$ and $\alpha = 50\%$ breakdown point are considered.

First of all, note that there is no real efficiency gain using MCD² instead of MCD¹, at least for $\alpha = 0.25$. In the 50% breakdown case, where the efficiency of the initial estimator MCD is very low (cfr. Figure 2), two times reweighting may be an option. A comparison with Tables 2 and 3 learns that a considerable asymptotic efficiency gain is obtained by reweighting the MCD-estimator. Also at the heavier tailed Student distributions, MCD¹ is more precise than ordinary MCD. As a preliminary conclusion, one can say that the one

step reweighted 25% breakdown MCD seems to be the best out of the class of MCD-based estimators.

On the other hand, the 25% breakdown S-estimator outperforms all the others in the normal case and under the Student distribution. Using the reweighted S-estimator for efficiency reasons has not much sense, unless for $\alpha = 50\%$ and p small. The ordinary S-estimator combines a high efficiency with a high breakdown point, yielding a very appealing estimator. Rocke (1996) noticed that the efficiency of S -estimators tends to 100% when the dimension tends to infinity, but argued that S-estimators are in fact not so robust since their *asymptotic rejection probability* is extremely small in high dimensions. One may not forget that a positive breakdown point is not a guarantee for robustness, since the corresponding bias may become extremely large, but still remain bounded.

5 Finite Sample Efficiencies

The results given in the preceding sections are of an asymptotic nature. In this section, finite-sample efficiencies for the MCD, S and their reweighted versions are obtained by means of a simulation study. Both estimators are defined as minimizers of a certain criterion under an additional constraint, implying that it is not so obvious to compute them in practice. Fortunately, algorithms were proposed which give excellent approximations to the actual value of the estimator. For computing the MCD the FAST-MCD algorithm of Rousseeuw and Van Driessen (1997) was used, while S -estimators are based on the SURREAL algorithm of Ruppert (1992). Both algorithms start from an initial mean and covariance matrix obtained from a $(p+1)$ subset of observations, which is iterated towards better approximations using Newton-steps (for S) or C -steps (for MCD). This choice for the starting values guarantees that the computed version of the estimator shares the robustness properties of the theoretical counterpart. Implementation of the algorithms was done in GAUSS and in both cases 500 different starting values were considered for each computation of the estimator. To illustrate the fastness of the algorithms: at a (50×5) normal data set it took about one second to compute the MCD and half a second for the S -estimator on a Pentium 200Mhz. One may certainly say that computational feasibility is no longer an obstacle for the use of high breakdown methods. Furthermore, note that reweighting the estimators comes at almost no additional computational cost.

For $m = 5000$ samples of sizes $n = 50$ and 200 , observations were generated from a $N(0, I_p)$ with $p = 2, 3, 5$ or 10 . Denote $\hat{\Sigma}_{ij}^k$ the element (i, j) of the estimator obtained from the k th sample, with $1 \leq k \leq m$. The accuracy of a diagonal element is measured by the *standardized variance*

$$\text{StVar}(\hat{\Sigma}_{ii}) = \frac{n \text{var}_m(\hat{\Sigma}_{ii})}{[\text{ave}_m(\hat{\Sigma}_{ii})]^2}, \quad (5.1)$$

where $\text{ave}_m(\hat{\Sigma}_{ii})$ and $\text{var}_m(\hat{\Sigma}_{ii})$ are the average and standard deviation computed from the sequence of m replicates $\hat{\Sigma}_{ij}^k$. (Use of measure (5.1) is motivated by Bickel and Lehmann, page 1142, 1976). For an off-diagonal element the mean squared error (MSE) is used to measure the deviation from the true value:

$$\text{MSE}(\hat{\Sigma}_{ij}) = \frac{n}{m} \sum_{k=1}^m (\hat{\Sigma}_{ij}^k - I_{ij})^2, \quad (5.2)$$

with I_{ij} of course equal to zero for $i \neq j$.

The simulation results are summarized in Tables 7 and 8. Since 2 is the lower bound for (5.1), the reported efficiencies in Table 7 equal $2/\text{ave}_p \text{StVar}(\hat{\Sigma}_{ii})$. Efficiencies for the off-diagonal elements are obtained in a similar way, now with 1 as lower bound.

First off all, note that the finite-sample efficiencies of the MCD converge well to the asymptotic ones which are listed under $n = \infty$ in the Tables. There is some discrepancy for $p = 10$, which enforces the idea that convergence to the asymptotic distribution is slower in higher dimensions. For the one step reweighted MCD there is quite serious loss of efficiency at finite samples, certainly for $p = 5$ and $p = 10$, but it still dominates the ordinary MCD. We can repeat the conclusions of Section 4 here: (a) reweighted MCD with $\alpha = 0.25$ yields very reasonable efficiencies (b) 25% breakdown S-estimators have the highest efficiencies among the considered estimators: almost always above 90% (c) reweighting an S-estimator (except for p small and $\alpha = 0.5$) leads to a small loss in precision.

Since the MCD and S estimators are meant to be robust estimators of multivariate location and scatter, we compared their behavior at a contaminated normal distribution. The generated samples contain now 20% of outliers equal to $100 \vec{e}_1$ where \vec{e}_1 is the first unit vector, while the remaining 80% observations are again normally distributed. The contamination will affect the whole scatter-matrix, and MSEs defined by (5.2) have been computed.

In Tables 9 and 10, results for two representative cases, $\text{MSE}(\hat{\Sigma}_{11})$ and $\text{MSE}(\hat{\Sigma}_{12})$ are reported for the 25% and 50% breakdown point MCD, MCD¹, S and S^1 estimators. One sees that the reweighted MCD remains much more precise than its initial estimator, even under severe contamination. Although the percentage of outliers is close to the breakdown point of the MCD¹ estimator with $\alpha = 0.25$, the MSE of the latter is comparable to the MSE of the maximal breakdown point MCD¹. The S -estimator with $\alpha = 0.25$, which was the most efficient in the uncontaminated case, becomes very unstable at the 20% contamination level. On the other hand, the reweighted S -estimator is much more robust. The (small) loss in efficiency paid for by reweighting the S -estimator, is apparently compensated by a gain in robustness. This in contrast with the MCD, where the reweighted version performs better both in presence and absence of contamination.

To conclude the simulation study, one could say that reweighted S and MCD with 25% breakdown are the most appealing among all considered estimators. Comparing MCD¹ with S^1 is slightly favorable for the latter due to its better efficiency at the normal model, especially at finite samples in higher dimensions. Let us not forget, however, the very intuitive finite-sample definition of the MCD, which could make the MCD¹ more attractive to non-specialists in the field.

6 Conclusion

The development and availability of fast algorithms (Hawkins 1994, Rousseeuw and Van Driessen 1997) for computing the Minimum Covariance Determinant (MCD) has brought renewed interest to this estimator. Asymptotic properties were given in Butler, Davies and Jhun (1993), but the asymptotic variance of the MCD-scatter part remained unknown. In this paper, we worked out the influence function of the Minimum Covariance Determinant (MCD) scatter matrix estimator and used it to evaluate the asymptotic relative efficiency of this robust estimator w.r.t. the classical scatter estimator. The efficiencies of other robust estimators, whose influence function has already been derived in the literature, i.e. the S-estimator and reweighted estimators, have also been evaluated numerically .

The main conclusion is that the Gaussian efficiency of the maximal breakdown MCD estimator is rather poor, but is already substantially higher for the 25% breakdown MCD and increases even more after reweighting. The efficiency of the reweighted MCD with $\alpha = 0.25$ seems to be acceptable: almost always above 60% in the Gaussian case, even for finite samples.

With respect to efficiency, 25% breakdown S-estimators are very attractive and outperform the reweighted MCD estimators. Davies (1992b) and Lopuhaä (1991) proposed alternatives to S-estimators with a higher efficiency, but these improvements seem only to be worthwhile in the 50% breakdown point case with p small. In spite of their positive breakdown property, the bias of S -estimators can be considerably high. Yohai and Maronna

(1990) showed this by means of the *Maxbias curve*, which is a powerful tool to quantify the robustness of an estimator. It is therefore not sufficient to consider only breakdown point and efficiency of robust estimators, also Maxbias curves should be computed. This has been done for the MCD-estimator in the univariate case (Croux and Haesbroeck 1998), but the multivariate case seems to be rather hard to handle.

To keep the scope of the study limited, many other estimators of multivariate scatter have not been included in the comparative part of this study. An overview of several other robust estimators of multivariate location and scatter is presented by Maronna and Yohai (1998).

7 Appendix

Proof of Proposition 1: Call $G = F_{\varepsilon, x}$, $t_\varepsilon = T_{(A, y)}(G)$, $\Sigma_\varepsilon = \Sigma_{(A, y)}(G)$ and $d_\varepsilon^2(z) = (z - t_\varepsilon)' \Sigma_\varepsilon^{-1} (z - t_\varepsilon)$. Define for every $s > 0$

$$\mathcal{E}_s = \{z \in \mathbb{R}^p \mid d_\varepsilon^2(z) < s\},$$

denote

$$D^2(G) = \sup\{s > 0 \mid P_G(\mathcal{E}_s) \leq 1 - \alpha\},$$

and take $\mathcal{E} = \mathcal{E}_{D^2(G)}$. Since $\lim_{s \rightarrow \infty} P_G(\mathcal{E}_s) > 1 - \alpha$ and $\lim_{s \rightarrow 0} P_G(\mathcal{E}_s) \leq \varepsilon < 1 - \alpha$, \mathcal{E} is a well defined, bounded and non degenerate open ellipsoid with $1 - \alpha - \varepsilon \leq P_G(\mathcal{E}) \leq 1 - \alpha$. We conclude that $\mathcal{E} \in \mathcal{D}_G(\alpha)$ or $(\mathcal{E}, x) \in \tilde{\mathcal{D}}_G(\alpha)$, since x is the only atom of the distribution G .

Consider the two following probability measures $\nu_{(A, y)}$ and $\nu_{(\mathcal{E}, x)}$ defined for each measurable set B by

$$\nu_{(A, y)}(B) = (P_G(A \cap B) + \delta I(y \in B)) / (1 - \alpha),$$

with $\delta = 1 - \alpha - P_G(A)$ and

$$\nu_{(\mathcal{E}, x)}(B) = (P_G(\mathcal{E} \cap B) + \tilde{\delta} I(x \in B)) / (1 - \alpha),$$

where $\tilde{\delta} = 1 - \alpha - P_G(\mathcal{E})$. By definition of \mathcal{E} one has that $\tilde{\delta} = 0$, unless if the atom x lies at the border of \mathcal{E} . Therefore

$$\tilde{\delta} (d_\varepsilon^2(x) - D^2(G)) = 0. \tag{7.1}$$

It is sufficient to show that

$$E_{\nu_{(\mathcal{E},x)}}[d_\varepsilon^2(z)] \leq E_{\nu_{(A,y)}}[d_\varepsilon^2(z)]. \quad (7.2)$$

Indeed, if the above equation holds, we know that there exists a $0 < c \leq 1$ for which

$$E_{\nu_{(\mathcal{E},x)}}[(z - t_\varepsilon)^t (c\Sigma_\varepsilon)^{-1} (z - t_\varepsilon)] = p, \quad (7.3)$$

since the RHS of (7.2), like the sum of the diagonal elements of the hat matrix, equals p . Since (A, y) provides an MCD solution we have that $\det(c\Sigma_\varepsilon) \leq \det(\Sigma_\varepsilon) \leq \det(\Sigma_{(\mathcal{E},x)}(G))$, which in combination with (7.3) contradicts the result of Grübel (1988) unless $t_\varepsilon = T_{(\mathcal{E},x)}(G)$, and $c\Sigma_\varepsilon = \Sigma_{(\mathcal{E},x)}(G)$. Then also c should equal 1, which will end the proof.

To prove (7.2), write

$$E_{\nu_{(\mathcal{E},x)}}[d_\varepsilon^2(z)] = \frac{1}{1-\alpha} \left\{ \int_{\mathcal{E} \cap A} d_\varepsilon^2(z) dG(z) + \int_{\mathcal{E} \setminus (A \cup \{y\})} d_\varepsilon^2(z) dG(z) + d_\varepsilon^2(y) P_G(\mathcal{E} \cap \{y\}) + \tilde{\delta} d_\varepsilon^2(x) \right\}. \quad (7.4)$$

Now

$$\begin{aligned} \int_{\mathcal{E} \setminus (A \cup \{y\})} d_\varepsilon^2(z) dG(z) &\leq D^2(G) P_G(\mathcal{E} \setminus (A \cup \{y\})) \\ &= D^2(G) (1 - \alpha - \tilde{\delta} - P_G(\mathcal{E} \cap A) - P_G(\mathcal{E} \cap \{y\})) \\ &= D^2(G) (P_G(A \setminus \mathcal{E}) + \delta - \tilde{\delta} - P_G(\mathcal{E} \cap \{y\})) \\ &\leq \int_{A \setminus \mathcal{E}} d_\varepsilon^2(z) dG(z) + D^2(G) (\delta - \tilde{\delta} - P_G(\mathcal{E} \cap \{y\})). \end{aligned} \quad (7.5)$$

Combining (7.4) and (7.5) with (7.1), yields

$$\begin{aligned} E_{\nu_{(\mathcal{E},x)}}[d_\varepsilon^2(z)] &\leq \frac{1}{1-\alpha} \left\{ \int_A d_\varepsilon^2(z) dG(z) + D^2(G) (\delta - P_G(\mathcal{E} \cap \{y\})) + d_\varepsilon^2(y) P_G(\mathcal{E} \cap \{y\}) \right\} \\ &= E_{\nu_{(A,y)}}[d_\varepsilon^2(z)] + \frac{1}{1-\alpha} \{ (D^2(G) - d_\varepsilon^2(y)) (\delta - P_G(\mathcal{E} \cap \{y\})) \} \end{aligned} \quad (7.6)$$

The second term of (7.6) is always negative, since $D^2(G) \leq d_\varepsilon^2(y)$ for $y \notin \mathcal{E}$ and $D^2(G) \geq d_\varepsilon^2(y)$, but $\delta \leq P_G(\{y\})$ for $y \in \mathcal{E}$. Therefore, (7.2) holds. \square

Proof of theorem 1: For ease of notation, denote $F_{\varepsilon,x_0} = (1-\varepsilon)F + \varepsilon\Delta_{x_0}$, where x_0 is an arbitrary point, $\Sigma(F_{\varepsilon,x_0}) = \Sigma_\varepsilon$ and $T(F_{\varepsilon,x_0}) = t_\varepsilon$. Proposition 1 guarantees that the MCD

scatter estimator at F_{ε, x_0} satisfies

$$\begin{aligned}\Sigma_\varepsilon &= c_\alpha \left\{ \frac{1}{1-\alpha} \int_{A(F_{\varepsilon, x_0})} x x^t dF_{\varepsilon, x_0}(x) - t_\varepsilon t_\varepsilon^t \right\} \\ &= c_\alpha \left\{ \frac{1-\varepsilon}{1-\alpha} \int_{A(F_{\varepsilon, x_0})} x x^t dF(x) + \frac{\varepsilon}{1-\alpha} \mathbf{I}(x_0 \in A(F_{\varepsilon, x_0})) x_0 x_0^t - t_\varepsilon t_\varepsilon^t \right\},\end{aligned}$$

where $A(F_{\varepsilon, x_0}) = \{x \in \mathbb{R}^p : (x - t_\varepsilon)^t \Sigma_\varepsilon^{-1} (x - t_\varepsilon) < q_\alpha(\varepsilon)\}$, for a certain positive number $q_\alpha(\varepsilon)$. (As long as $\|x_0\| \neq q_\alpha$ one may suppose that x_0 does not belong to the border of $A(F_{\varepsilon, x_0})$ for ε small, cfr. Remark 4, Section 2.) By definition, $IF(x_0, \Sigma, F) = \frac{\partial \Sigma_\varepsilon}{\partial \varepsilon} \Big|_{\varepsilon=0}$. Let us differentiate Σ_ε w.r.t. ε and set $\varepsilon = 0$:

$$\begin{aligned}\frac{\partial \Sigma_\varepsilon}{\partial \varepsilon} \Big|_{\varepsilon=0} &= c_\alpha \left\{ -\frac{1}{1-\alpha} \int_{A(F)} x x^t dF(x) + \frac{1}{1-\alpha} \frac{\partial}{\partial \varepsilon} \int_{A(F_{\varepsilon, x_0})} x x^t dF(x) \Big|_{\varepsilon=0} \right. \\ &\quad \left. + \frac{1}{1-\alpha} \mathbf{I}(x_0 \in A(F)) x_0 x_0^t \right\}.\end{aligned}\tag{7.7}$$

Using the Fisher consistency of $\Sigma(F)$ and the fact that $A(F) = \{x \in \mathbb{R}^p : x^t x \leq q_\alpha\}$, we get

$$IF(x_0, \Sigma, F) = -I + \frac{c_\alpha}{1-\alpha} \frac{\partial}{\partial \varepsilon} \int_{A(F_{\varepsilon, x_0})} x x^t dF(x) \Big|_{\varepsilon=0} + \frac{c_\alpha}{1-\alpha} \mathbf{I}(\|x_0\|^2 \leq q_\alpha) x_0 x_0^t.\tag{7.8}$$

In order to compute the second term on the right hand side of (7.8), which will be abbreviated by $I(\varepsilon)$, we transform the integration variable x to $y = \Sigma_\varepsilon^{-\frac{1}{2}}(x - t_\varepsilon)$. The integration domain becomes now a ball with center at the origin and radius $\sqrt{q_\alpha(\varepsilon)}$. When more convenient, we will express y in polar coordinates $y = r e(\theta)$ with $r \in [0, \sqrt{q_\alpha(\varepsilon)}]$, $e(\theta) \in S^{p-1}$ and $\theta = (\theta_1, \dots, \theta_{p-1}) \in \Theta = [0, \pi[\times \dots [0, \pi[\times [0, 2\pi[$. This yields

$$I(\varepsilon) = \det(\Sigma_\varepsilon^{\frac{1}{2}}) \int_0^{\sqrt{q_\alpha(\varepsilon)}} \int_\Theta J(\theta, r) (r \Sigma_\varepsilon^{\frac{1}{2}} e(\theta) + t_\varepsilon) (r \Sigma_\varepsilon^{\frac{1}{2}} e(\theta) + t_\varepsilon)^t g((r \Sigma_\varepsilon^{\frac{1}{2}} e(\theta) + t_\varepsilon)^t (r \Sigma_\varepsilon^{\frac{1}{2}} e(\theta) + t_\varepsilon)) dr d\theta,\tag{7.9}$$

where $J(\theta, r)$ is the Jacobian of the transformation into polar coordinates.

By matrix differentiation and since $\Sigma_0 = I$, we obtain

$$\frac{\partial \det(\Sigma_\varepsilon^{\frac{1}{2}})}{\partial \varepsilon} \Big|_{\varepsilon=0} = \frac{1}{2} \frac{\partial \det(\Sigma_\varepsilon)}{\partial \varepsilon} \Big|_{\varepsilon=0} = \frac{1}{2} \text{trace}(IF(x_0, \Sigma, F))\tag{7.10}$$

Applying Leibniz' formula to (7.9) and using (7.10) results in

$$\begin{aligned}\frac{\partial I(\varepsilon)}{\partial \varepsilon} \Big|_{\varepsilon=0} &= \frac{1}{2} \text{trace}(IF(x_0, \Sigma, F)) H(q_\alpha) I + \frac{\partial \sqrt{q_\alpha(\varepsilon)}}{\partial \varepsilon} \Big|_{\varepsilon=0} q_\alpha g(q_\alpha) d_1 I \\ &\quad + \int_{\|y\|^2 \leq q_\alpha} \frac{\partial}{\partial \varepsilon} \left((\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon) (\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon)^t g((\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon)^t (\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon)) \right) \Big|_{\varepsilon=0} dy,\end{aligned}\tag{7.11}$$

with $d_1 = \int_{\Theta} J(\theta, \sqrt{q_\alpha}) e_1^2(\theta) d\theta = \frac{1}{p} \int_{\Theta} J(\theta, \sqrt{q_\alpha}) d\theta$ and $H(q_\alpha) = \int_{\|y\|^2 \leq q_\alpha} y_1^2 g(y^t y) dy = \left(\frac{c_\alpha}{1-\alpha}\right)^{-1}$.

The derivative in the third term of (7.11) is given by

$$\begin{aligned} & \frac{\partial}{\partial \varepsilon} \left((\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon) (\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon)^t g((\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon) (\Sigma_\varepsilon^{\frac{1}{2}} y + t_\varepsilon)) \right) \Big|_{\varepsilon=0} \\ &= \frac{1}{2} \left\{ IF(x_0, \Sigma, F) y y^t + y y^t IF(x_0, \Sigma, F) + 2 IF(x_0, T, F) y^t + 2 y IF(x_0, T, F)^t \right\} g(y^t y) \\ &+ y y^t g'(y^t y) \left\{ y^t IF(x_0, \Sigma, F) y + 2 y^t IF(x_0, T, F) \right\}. \end{aligned} \quad (7.12)$$

Note that since $\int_{\|y\|^2 \leq q_\alpha} y g(y^t y) dy$ and $\int_{\|y\|^2 \leq q_\alpha} y y^t g'(y^t y) y dy$ are zero, the terms in (7.12) including $IF(x_0, T, F)$ give a zero contribution to the integral in (7.11).

Equation (7.11) still depends on $\frac{\partial \sqrt{q_\alpha(\varepsilon)}}{\partial \varepsilon} \Big|_{\varepsilon=0}$ which needs to be computed. By definition of $A(F_{\varepsilon, x_0})$,

$$1 - \alpha = \int_{A(F_{\varepsilon, x_0})} dF_{\varepsilon, x_0}(x) = (1 - \varepsilon) \int_{A(F_{\varepsilon, x_0})} dF(x) + \varepsilon \mathbf{I}(x_0 \in A(F_{\varepsilon, x_0})). \quad (7.13)$$

Differentiating both sides w.r.t. ε yields

$$0 = - \int_{A(F)} dF(x) + \frac{\partial}{\partial \varepsilon} \int_{A(F_{\varepsilon, x_0})} dF(x) \Big|_{\varepsilon=0} + \mathbf{I}(\|x_0\|^2 \leq q_\alpha). \quad (7.14)$$

In the same way as before, one can easily verify that

$$\begin{aligned} \frac{\partial}{\partial \varepsilon} \int_{A(F_{\varepsilon, x_0})} dF(x) \Big|_{\varepsilon=0} &= \frac{1 - \alpha}{2} \text{trace}(IF(x_0, \Sigma, F)) + \frac{\partial \sqrt{q_\alpha(\varepsilon)}}{\partial \varepsilon} \Big|_{\varepsilon=0} g(q_\alpha) \int_{\Theta} J(\theta, \sqrt{q_\alpha}) d\theta \\ &+ \int_{\|y\|^2 \leq q_\alpha} g'(y^t y) y^t IF(x_0, \Sigma, F) y dy. \end{aligned} \quad (7.15)$$

The last term in (7.15) equals, using the symmetry of F , $c_2 \text{trace}(IF(x_0, \Sigma, F))$, with $c_2 = \int_{\|y\|^2 \leq q_\alpha} y_1^2 g'(y^t y) dy$.

By substituting (7.15) in (7.14), the above equation leads to

$$\frac{\partial \sqrt{q_\alpha(\varepsilon)}}{\partial \varepsilon} \Big|_{\varepsilon=0} = \frac{1 - \alpha - \mathbf{I}(\|x_0\|^2 \leq q_\alpha) - \text{trace}(IF(x_0, \Sigma, F))(c_2 + \frac{1-\alpha}{2})}{g(q_\alpha) p d_1}. \quad (7.16)$$

Inserting (7.16) and (7.12) in (7.11) gives

$$\begin{aligned} IF(x_0, \Sigma, F) &= -I + \frac{c_\alpha}{1-\alpha} \mathbf{I}(\|x_0\|^2 \leq q_\alpha) x_0 x_0^t + \frac{1}{2} \text{trace}(IF(x_0, \Sigma, F)) I \\ &+ \frac{c_\alpha}{1-\alpha} \frac{q_\alpha}{p} \left((1 - \alpha) - \mathbf{I}(\|x_0\|^2 \leq q_\alpha) - \text{trace}(IF(x_0, \Sigma, F))(c_2 + \frac{1-\alpha}{2}) \right) I \\ &+ \frac{c_\alpha}{2(1-\alpha)} \int_{\|y\|^2 \leq q_\alpha} (IF(x_0, \Sigma, F) y y^t + y y^t IF(x_0, \Sigma, F)) g(y^t y) dy \\ &+ \frac{c_\alpha}{1-\alpha} \int_{\|y\|^2 \leq q_\alpha} y y^t g'(y^t y) y^t IF(x_0, \Sigma, F) y dy. \end{aligned} \quad (7.17)$$

In order to give element wise expressions for the influence function, we note that

$$\begin{aligned} & \frac{1}{2} \sum_{k=1}^p \left\{ IF(x_0, \Sigma_{ik}, F) \int_{\|y\|^2 \leq q_\alpha} y_k y_j g(y^t y) dy + IF(x_0, \Sigma_{kj}, F) \int_{\|y\|^2 \leq q_\alpha} y_i y_j k g(y^t y) dy \right\} \\ &= H(q_\alpha) IF(x_0, \Sigma_{ij}, F) \end{aligned}$$

for every $1 \leq i, j \leq p$ and

$$\begin{aligned} & \sum_{k=1}^p \sum_{l=1}^p IF(x_0, \Sigma_{kl}, F) \int_{\|y\|^2 \leq q_\alpha} y_i y_j y_k y_l g'(y^t y) dy \\ &= \begin{cases} c_3 \text{trace}(IF(x_0, \Sigma, F)) + (c_4 - c_3) IF(x_0, \Sigma_{ii}, F) & i = j \\ 2c_3 IF(x_0, \Sigma_{ii}, F) & i \neq j \end{cases} \end{aligned}$$

where $c_3 = \int_{\|y\|^2 \leq q_\alpha} y_i^2 y_j^2 g'(y^t y) dy$ and $c_4 = \int_{\|y\|^2 \leq q_\alpha} y_i^4 g'(y^t y) dy$.

The constants c_2, c_3 and c_4 can be rewritten in the form given in the statement of the theorem, using polar coordinates. From (7.17) the influence function for the off-diagonal elements is immediately obtained:

$$IF(x_0, \Sigma_{ij}, F) = \frac{c_\alpha x_{0i} x_{0j}}{1 - \alpha} I(\|x_0\|^2 \leq q_\alpha) + \frac{c_\alpha}{1 - \alpha} (2c_3 + H(q_\alpha)) IF(x_0, \Sigma_{ij}, F),$$

which leads to (2.13), due to the definition of H . For the diagonal elements, we get

$$\begin{aligned} IF(x_0, \Sigma_{jj}, F) &= -1 + \frac{c_\alpha x_{0j}^2}{1 - \alpha} I(\|x_0\|^2 \leq q_\alpha) + \frac{1}{2} \text{trace}(IF(x_0, \Sigma, F)) \\ &+ \frac{c_\alpha}{1 - \alpha} \frac{q_\alpha}{p} \left\{ (1 - \alpha) - I(\|x_0\|^2 \leq q_\alpha) - \text{trace}(IF(x_0, \Sigma, F)) (c_2 + \frac{1 - \alpha}{2}) \right\} \\ &+ \frac{c_\alpha}{1 - \alpha} \{c_4 - c_3 + H(q_\alpha)\} IF(x_0, \Sigma_{jj}, F) + \frac{c_\alpha c_3}{1 - \alpha} \text{trace}(IF(x_0, \Sigma, F)) \end{aligned} \quad (7.18)$$

Using the constants b_1 and b_2 defined in Section 2, (7.18) can be written as follows:

$$\begin{aligned} & b_1 IF(x_0, \Sigma_{jj}, F) - b_2 \text{trace}(IF(x_0, \Sigma, F)) \\ &= -1 + \frac{c_\alpha x_{0j}^2}{1 - \alpha} I(\|x_0\|^2 \leq q_\alpha) + \frac{c_\alpha}{1 - \alpha} \frac{q_\alpha}{p} \left\{ 1 - \alpha - I(\|x_0\|^2 \leq q_\alpha) \right\}. \end{aligned} \quad (7.19)$$

Taking the sum of the diagonal terms given in (7.19) yields the trace of the influence function

$$\text{trace}(IF(x_0, \Sigma, F)) = \frac{\frac{c_\alpha \|x_0\|^2}{1 - \alpha} I(\|x_0\|^2 \leq q_\alpha) + p \left\{ \frac{c_\alpha}{1 - \alpha} \frac{q_\alpha}{p} (1 - \alpha - I(\|x_0\|^2 \leq q_\alpha)) - 1 \right\}}{b_1 - p b_2}. \quad (7.20)$$

Combining (7.19) and (7.20) gives (2.12). \square
